ASSOCIATION BETWEEN GLUCOCORTICOID THERAPY AND Incidence OF DIABETES MELLITUS IN POLYMYALGIA RHEUMATICA AND giant cell arteritis: A SYSTEMATIC REVIEW AND META-ANALYSIS

Lana Yin Hui Lai, Emma Harris, Robert M West, Sarah Louise Mackie

ABSTRACT

Background Polymyalgia rheumatica (PMR) and giant cell arteritis (GCA) are almost always treated with glucocorticoids (GCs), but long-term GC use is associated with diabetes mellitus (DM). The absolute incidence of this complication in this patient group remains unclear.

Objective To quantify the absolute risk of GC-induced DM in PMR and GCA from published literature.

Methods We identified literature from inception to February 2017 reporting diabetes following exposure to oral GC in patients with PMR and/or GCA without pre-existing diabetes. A random-effects meta-analysis was performed to summarise the findings.

Results 25 eligible publications were identified. In studies of patients with GCA, mean cumulative GC dose was almost 1.5 times higher than in studies of PMR (8.2 g vs 5.6 g), with slightly longer treatment duration and longer duration of follow-up (6.4 years vs 4.4 years). The incidence proportion (cumulative incidence) of patients who developed new-onset DM was 6% (95% CI 3% to 9%) for PMR and 13% (95% CI 9% to 17%) for GCA. Based on UK data on incidence rate of DM in the general population, the expected background incidence rate of DM over 4.4 years in patients with PMR and 6.4 years in patients with GCA (follow-up duration) would be 4.8% and 7.0%, respectively. Heterogeneity between studies was high (I² = 79.1%), as there were differences in study designs, patient population, geographical locations and treatment. Little information on predictors of DM was found.

Conclusion Our meta-analysis produced plausible estimates of DM incidence in patients with PMR and GCA, but there is insufficient published data to allow precise quantification of DM risk.

INTRODUCTION

Polymyalgia rheumatica (PMR) is a glucocorticoid (GC)-responsive condition causing bilateral shoulder and pelvic girdle pain and stiffness in older people. PMR is one of the most common reasons for long-term GC treatment in the community. Giant cell arteritis (GCA) is also treated with long-term GCs, but at higher doses, and is the most common primary systemic vasculitis affecting individuals aged over 50 years. The UK incidence of PMR is 8.4/10 000 person-years and of GCA is 2.2/10 000 person-years. Both diseases have a female:male ratio of 2–3:1 and similar age distribution, with incidence peaking in the eighth decade of life. This age group is particularly vulnerable to the adverse effects of GC, which relate both to dose and duration of therapy; the majority of patients with PMR and GCA experience GC-associated adverse effects. The most worrisome of these for both patients and rheumatologists is preexisting diabetes mellitus, though the absolute risk of developing DM is unclear.

What is already known about this subject?

- Polymyalgia rheumatica (PMR) and giant cell arteritis (GCA) are inflammatory disorders of the elderly, with glucocorticoids (GC) being the treatment of choice.

What does this study add?

- Our meta-regression suggests that the incidence proportion (cumulative incidence) of patients who developed new-onset DM was 6% (95% CI 3% to 9%) for PMR and 13% (95% CI 9% to 17%) for GCA, which is plausible, though there is insufficient published data to allow precise quantification of DM risk.

How might this impact on clinical practice?

- Findings from this study underline the importance of screening for GC-induced DM in patients with GCA/PMR in clinical practice and can also help inform dietary and lifestyle advice in patients taking GCs for GCA or PMR.

Key messages
diabetes mellitus (DM). Long-standing DM is associated with complications such as chronic kidney disease, retinopathy, diabetic neuropathy and so on, which often lead to a decline in quality of life, as well as marked shortening of life expectancy. This is also significant from a health economic perspective as it incurs significant additional healthcare utilisation. Despite the importance of this for patients, physicians and payers, there is currently minimal information on what the absolute risk of diabetes is in this particular patient group and which patients are at the greatest risk of developing new-onset diabetes while taking GC for PMR or GCA. Quantification of the costs and burdens of GC adverse effects allows assessment of the benefit of new therapies intended to reduce GC exposure while maintaining disease control.

It is recommended that clinicians take comorbidity and prognostic risk factors into account when making treatment decisions, but as regards for risk of DM, clinicians must rely on indirect evidence extrapolated from other populations, such that the strength of the evidence for this would need to be downgraded for clinical guidelines. We aimed to collate published literature that could help to answer this question.

**METHODS**

**Search strategy**

We searched for published studies or conference abstracts indexed in PubMed, Ovid (Medline and Embase), Web of Science, Cochrane Library and Cumulative Index of Nursing and Allied Health Literature from inception to February 2017. The search included terms for patients with PMR and/or GCA who were prescribed oral GC therapy, as well as diabetes-related terms as some individuals eventually developed diabetes. The full search strategy is available in online supplementary appendix 1. We also manually screened reference lists of selected retrieved articles to identify further papers that may have been missed in the database search. We made every effort to include all available studies and conference abstracts (regardless of publication year), which included contacting the first authors by email if necessary. The selection process of identifying relevant studies is shown in figure 1.

**Eligibility criteria**

We identified original research articles, conference abstracts and grey literature that reported diabetes
following exposure to oral GC therapy. The populations of interest were patients with a diagnosis of PMR and/or GCA with no pre-existing diabetes. We assume that, if not otherwise stated, all patients with PMR or GCA were treated with GCs. We included all randomised controlled trials, cohort studies, cross-sectional studies and case-control studies. Case series and case reports were excluded. There was no language restriction. Non-English articles were translated with the help of Google Translate and colleagues who were native speakers of the respective languages.

**Study selection**

Two investigators (LYHL and EH) independently carried out the initial screening of search results by title and abstract, using the abstract screen software ‘Abstrackr’\(^\text{11}\) and Endnote X7.4 (1988–2015 Thomson Reuters). Study eligibility was determined independently, and any disagreements were resolved by consensus with the third investigator (SLM).

**Data extraction**

Data were extracted independently by LYHL and EH using a standardised data collection Microsoft Access database. Any discrepancies in data extraction were resolved by consensus. For articles containing more than one study group, we included the ‘GC-only’ arm and excluded the groups where there was another study drug in addition to GCs. We also performed a sensitivity analysis by incorporating all the study groups into our analysis. Information extracted included journal information, publication year, year of enrolment, study design, patient demographics (age, sex, body mass index, weight, height, medical history, family history, glucose level and HbA1c), number of patients recruited, number of patients with DM, definition of DM, GC indication, treatment dose and duration of follow-up. Patient populations were classified as ‘PMR’ or ‘GCA’ based on their primary diagnosis as determined by the authors. We only included studies where the authors identified ‘new-onset diabetes’ associated with GC use. We excluded any prediabetic states

DISCUSSION

There is overwhelming epidemiological and pathophysiological evidence that GC therapy may cause DM.\textsuperscript{15-19} Our aim was to estimate the effect size in this particular population for the purpose of informing clinical decisions about care of patients with PMR/GCA and health economic analyses about the cost-effectiveness of new therapies for PMR/GCA. In our meta-analysis of published literature, the estimated incidence proportion (cumulative incidence) of new-onset diabetes was

H, high risk of bias; L, lower risk of bias; U, unclear risk of bias.

Figure 2 Proportion of PMR and GCA patients who developed new-onset DM after GC use. GCA, giant cell arteritis; PMR, polymyalgia rheumatica.
6% (95% CI 3% to 9%) for patients with PMR and 13% (95% CI 9% to 17%) for patients with GCA. These figures are plausible: they are slightly higher than current UK population rates for patients of this age and sex, of which the expected background incidence rate of DM over 4.4 years in patients with PMR and 6.4 years in patients with GCA (follow-up duration) would be 4.8% and 7.0%, respectively.20 It should also be noted that many of the studies we reviewed were conducted at a time when population incidence of DM was lower than it is now.20 In addition, a few studies,21–25 including a recent meta-analysis,26 have shown that patients with GCA had a lower prevalence of DM at the time of GCA diagnosis compared with age-matched and sex-matched controls, which may suggest that the magnitude of GC-induced DM to be greater than expected. Two observational studies27 28 found no difference in pre-existing DM between patients with GCA and their comparison patients, while another two studies29 30 reported a higher prevalence of DM in the GCA cohort.

A very recent Danish study31 reported that the incidence risk ratio of new-onset DM was 7.0 (95% CI 5.2 to 9.3) in the GCA cohort during the first year of observation when compared with the general population. Beyond the first year, they reported that the incidence rates for DM were not significantly increased. In another large observational study of 5011 patients with GCA, the incidence risk ratios of DM was 1.4 (95% CI 1.2 to 1.7) as compared with matched non-GCA patients.32 The median time for the occurrence of DM in the GCA group was 1 year, which supports the hypothesis that the risk of developing GC-induced DM may be highest within the first year of GC use. Other datasets emphasise cumulative dose: a very recently published US study reported that the risk for new-onset DM rose 5% with each 1000 mg of GC exposure in patients with GCA.33

Heterogeneity in study design was high; the study populations were diverse in terms of disease manifestation, situated at different geographical locations and were also subjected to different treatment strategies. In
addition, the studies included in this meta-analysis were done over a span of 40 years, during which time clinical practice is likely to have changed. This heterogeneity was also reflected in high statistical heterogeneity identified by our meta-analysis as assessed by the $I^2$ and tau-squared, the DerSimonian-Laird estimate derived from a random effects model. One particular difficulty was the lack of clarity and consistency regarding the definition of DM in the studies identified. It was also difficult to identify the onset of DM as most of the studies (72%) did not specify whether DM developed during GC treatment or during the follow-up period.

Since most of the studies reviewed did not have the primary aim of quantifying DM risk in PMR/GCA, the detail available in published reports was limited. For example, summary measures such as mean starting dose, mean treatment duration and mean cumulative dose cannot fully capture the pattern of GC dosing used for PMR/GCA, where the highest GC burden occurs during the first 3 months.1,3,4

Because GCs are the mainstay of treatment for PMR and GCA, it was not possible to disentangle the effect of the disease from the effect of the treatment. It is however known that systemic inflammation itself can also induce a state of insulin resistance,7,35 so it is plausible that the inflammatory disease itself (PMR or GCA) could have contributed to the risk of new-onset DM. In addition, some medications commonly prescribed to elderly patients may contribute to the risk of DM (eg, thiazide diuretics, beta-blockers, niacins and statins). These were not reported by the studies identified, as their primary focus was not on DM.

Confounding by indication could not be excluded. For example, for the observational studies, clinicians may have been less willing to prescribe higher GC doses to control disease activity in obese patients at high risk of DM. We were also unable to exclude spurious association due to a possible detection/screening bias; longitudinally collected individual patient data would have been informative in this regard.

The overall risk of bias was high for many of the observational studies, especially for domains relating to the outcome and prognostic variables. Therefore, results should be interpreted with caution.

It is possible that studies that did not look for diagnoses of DM or found no cases of new onset DM would not have mentioned diabetes and therefore have been excluded from our search. This could have led to an over-estimate in the incidence of DM. Since DM has long been a concern with GC therapy, however, this is unlikely.

Our attempt to identify predictors of DM in this meta-analysis is more exploratory in nature as there are some limitations in the multivariable modelling. With this limited dataset and large number of potential explanatory variables, there is a risk of overfitting and may limit generalisability of this model. Other limitations of the model include the assumption that there is a linear relationship between variables, but it is also possible that collinearity may exist among some of the predictor variables. We excluded follow-up duration in our analysis because there is a high possibility that follow-up duration was confounded with diagnosis since patients with GCA are more likely to receive higher GC doses, thus tend to be monitored over a longer period of time.

CONCLUSION

Findings from this study underline the importance of screening for GC-induced DM in patients with GCA/PMR in clinical practice1,5 and can also help inform dietary and lifestyle advice in patients taking GC for GCA or PMR. As well as limitations inherent to the meta-analysis itself, there remains considerable uncertainty in our estimate of the absolute risk of DM in PMR/GCA, since most published studies were not conducted with this as the primary aim. Furthermore, there is virtually no direct evidence as to which patients are at the greatest risk of DM, which would inform decisions as to how treatment should be individualised. We suggest that further research should analyse individual patient data within large databases to generate clinically useful evidence to inform the next generation of clinical guidelines.
